ABSTRACT

Background This cross-sectional study aimed to examine whether appraisal of knee function, psychological and demographic factors were related to returning to the preinjury sport and recreational activity following anterior cruciate ligament (ACL) reconstruction.

Method 164 participants completed a questionnaire battery at 1–7 years after primary ACL reconstruction. The battery included questionnaires evaluating knee self-efficacy, health locus of control, psychological readiness to return to sport and recreational activity, and fear of reinjury; and self-reported knee function in sport-specific tasks, knee-related quality of life and satisfaction with knee function. The primary outcome was returning to the preinjury sport or recreational activity.

Results At follow-up, 40% (66/164) had returned to their preinjury activity. Those who returned had more positive psychological responses, reported better knee function in sport and recreational activities, perceived a higher knee-related quality of life and were more satisfied with their current knee function. The main reasons for not returning were not trusting the knee (28%), fear of a new injury (24%) and poor knee function (22%).

Psychological readiness to return to sport and recreational activity, measured with the ACL-Return to Sport after Injury scale (was most strongly associated with returning to the preinjury activity). Age, sex and preinjury activity level were not related.

Conclusions Less than 50% returned to their preinjury sport or recreational activity after ACL reconstruction.

Psychological readiness to return to sport and recreation was the factor most strongly associated with returning to the preinjury activity. Including interventions aimed at improving this in postoperative rehabilitation programmes could be warranted to improve the rate of return to sport and recreational activities.

INTRODUCTION

An important objective of anterior cruciate ligament (ACL) reconstruction is to enable patients to return to their preinjury sport or recreational activity. Despite this, the focus of the orthopaedic literature has been on evaluating impairment-based outcomes, such as knee stability, after reconstruction as a measure of the success of the surgery, while non-physical factors, including psychological factors, have been under-researched.^{1–2} From an impairment perspective, patients recover physical function well after surgery.³ However, between one-third and two-thirds of patients may not return to participation in their preinjury activity, despite

being physically recovered, when evaluated with standard objective instruments.^{3–6}

Objective physical recovery and returning to the preinjury sport and recreational activity may not necessarily coincide after ACL reconstruction,^{4–7} which raises the question of what other factors could impact on returning. Recent research has suggested that psychological factors may be important influences on returning to sport and recreation after athletic injury,^{8–9} but cautioned that because there are few studies examining the relationship between psychological factors and returning to sport and recreation, more research is needed to facilitate more definitive conclusions.⁹ The only meta-analysis of the relationship between psychological factors and returning to the preinjury sport following ACL reconstruction found large effects (standardised mean difference ≥ 0.9) for positive psychological responses favouring returning to sport, based on four studies.⁹

Psychological readiness to return to sport, recovery expectations, sport locus of control and self-efficacy regarding knee function are psychological factors that have been shown to predict returning to the preinjury sport at 12 months after ACL reconstruction;^{5–10} and self-efficacy of knee function, measured before surgery, has been shown to predict returning to physical activity at 1 year after ACL reconstruction.¹⁰ Fear of sustaining another injury has also been associated with not returning to the preinjury physical activity for up to 7 years after reconstruction,^{4–11–12} and is a common reason cited by athletes for not returning to sport and recreational activities.^{3–4–13–14}

People who did not have an ACL reconstruction after their ACL injury reported a positive relationship between their physical knee function and confidence in their knee, and stated that this had a positive impact on their participation in sport and recreational activities.¹⁴ However, to the best of our knowledge, this relationship has not been investigated in people who have had an ACL reconstruction. Previous studies have found no relationship between objective measures of physical impairment and patient-reported knee function following ACL reconstruction.^{15–17} In light of this, and the potential for an individual's report of knee function to impact on their return to sport and recreational activity after an ACL injury, it may be suggested that it is important to consider the impact of appraisals of knee function on returning to preinjury activity after reconstruction.

To cite: Ardern CL, Österberg A, Tagesson S, et al. *Br J Sports Med* 2014;**48**:1613–1619.

Participation in sport and recreational activity is complex and multifactorial; and there may be individual differences in the factors that impact on returning to participation in the preinjury activity following ACL reconstruction. Therefore, taking account of a range of psychological and contextual factors may improve our understanding of what influences returning to the preinjury activity, and help direct rehabilitation interventions aimed at improving the return to preinjury sport and recreational activity rate. Therefore, the aim of the current study was to examine whether appraisal of knee function, psychological and demographic factors were related to returning to the preinjury sport and recreational activity after ACL reconstruction.

METHOD

Design

This was a cross-sectional study, approved by the Regional Ethics Committee (Linköping University approval number: 2012/425–32). Written, informed consent to participate was obtained from all participants.

Participants

Participants were identified from two orthopaedic units (one tertiary teaching hospital and two local hospitals) in southeastern Sweden. The medical records of all patients with a knee injury diagnosis code of *chronic instability of the knee, dislocation of the knee, sprain or strain involving cruciate ligament of knee*, and *injury to multiple structures of the knee* recorded (International Classification of Diseases 10 codes M23.5, S83.1, S83.5, S83.7), and who were seen at the orthopaedic units between January 2004 and December 2008 were screened. Patients with non-operative treatment, bilateral injuries, revision surgery, other associated ligament pathology that required surgical treatment at the time of ACL reconstruction, or who had Outerbridge¹⁸ grade III or IV chondral injury were excluded (figure 1) to identify patients with a primary, uncomplicated ACL reconstruction. A total of 346 of 1447 patients met the inclusion criteria of age between 18 and 45 years at the time their medical record was reviewed, and 1–7 years after an isolated primary unilateral ACL reconstruction performed at either of the two orthopaedic units. Five patients declined to participate and 21 patients were unable to be contacted. Twelve patients had sustained a new knee injury between surgery and follow-up (figure 1).

Of the 182 patients (59% of 308) who responded, 164 were included in the final analysis for the current study. Data from 18 participants were excluded because the participants either did not participate in sport or recreational activity prior to their knee injury (n=9), or because they were active in recreational activities with a preinjury Tegner Activity Scale¹⁹ score of less than 4 (n=9; figure 1). An updated Tegner Activity Scale²⁰ with sports that were not included in the original scale was used to grade preinjury activity level in the current study. The scale rates activity level according to functional demands on the knee on an 11-level scale (scored from 0 to 10). Level 10 indicates the highest functional demand such as national or international level competitive football; level 7 indicates sports such as competitive tennis and recreational football; level 4 indicates sports such as recreational cycling or cross country skiing, and moderately heavy labour work; levels 3 to 1 indicate walking for recreation and light labour to sedentary work; and level 0 indicates no participation in physical activity due to knee problems.²⁰

Procedures

A battery of patient-reported outcomes, which took 30–40 min to complete, was sent by post to all eligible participants. Up to

three written reminders were sent over a 6-week period (2 weeks apart). Participants who had not completed the battery of patient-reported outcomes within 2 weeks were sent a reminder letter (and a new battery of outcomes). If they still had not responded within 2 weeks after the first reminder was sent, a second reminder letter was sent. A third and final reminder letter was sent to participants who had not returned the patient-reported outcomes within 6 weeks from the date the original questionnaire pack was sent. Participants completed the battery of outcomes, on average, at 35 months (range 12–81 months) after their ACL reconstruction surgery.

Outcome measures

The primary outcome was return to the preinjury sport or recreational activity. Participants reported the main activity they participated in before their ACL injury, and answered the question ‘Have you returned to your previous activity?’ Participants who reported that they had not returned to their preinjury activity were asked to rank the following reasons for not returning from most important to least important: ‘poor knee function’, ‘do not trust the knee’, ‘fear getting a new injury’, ‘team or training has changed’, ‘family commitments’, ‘work commitments’ and ‘other reasons’.

A battery of validated patient-reported outcomes was used to evaluate factors that may influence participation in the preinjury activity. The Swedish versions of all outcomes were used. Factors were chosen based on the researchers’ previous experience in the area of returning to sport and recreational activity after ACL reconstruction, and the findings of recently published literature. A systematic review of psychological factors associated with returning to sport following athletic injury⁸ was used to guide the selection of psychological factors, based on the theoretical constructs of competence, autonomy and relatedness. Psychological factors and appraisal of knee function factors with evidence of construct or known-groups validity in ACL reconstruction populations were chosen (online supplementary appendix). For analysis, the factors evaluated were grouped as psychological factors, appraisal of knee function factors and demographic factors. A detailed description of patient-reported outcomes, including their psychometric properties, is provided in the online supplementary appendix.

Explanatory variables

Psychological factors

The Knee Self-Efficacy Scale (K-SES)²¹ was used to evaluate participants’ self-efficacy of current and future knee function.

The Multidimensional Health Locus of Control C-form (MHLC-C)²² was used to evaluate the extent to which participants perceived their health was determined by their own behaviour, or by external events or people. The MHLC comprises four domains—*Internal*, *Chance*, *Doctors* and *Others*, reported as separate scores.

The ACL-Return to Sport after Injury scale (ACL-RSI)^{23 24} was used to evaluate psychological readiness to return to sport and recreational activity.

The Tampa Scale for Kinesiophobia (TSK),²⁵ adapted by Kvist *et al*¹¹ for use with patients with ACL injury, was used to evaluate fear of reinjury.

Appraisal of knee function

The *Sport* (five items) domain of the Knee Injury and Osteoarthritis Outcome Score (KOOS)²⁶ was used to evaluate participants’ perceptions of knee function during sport and

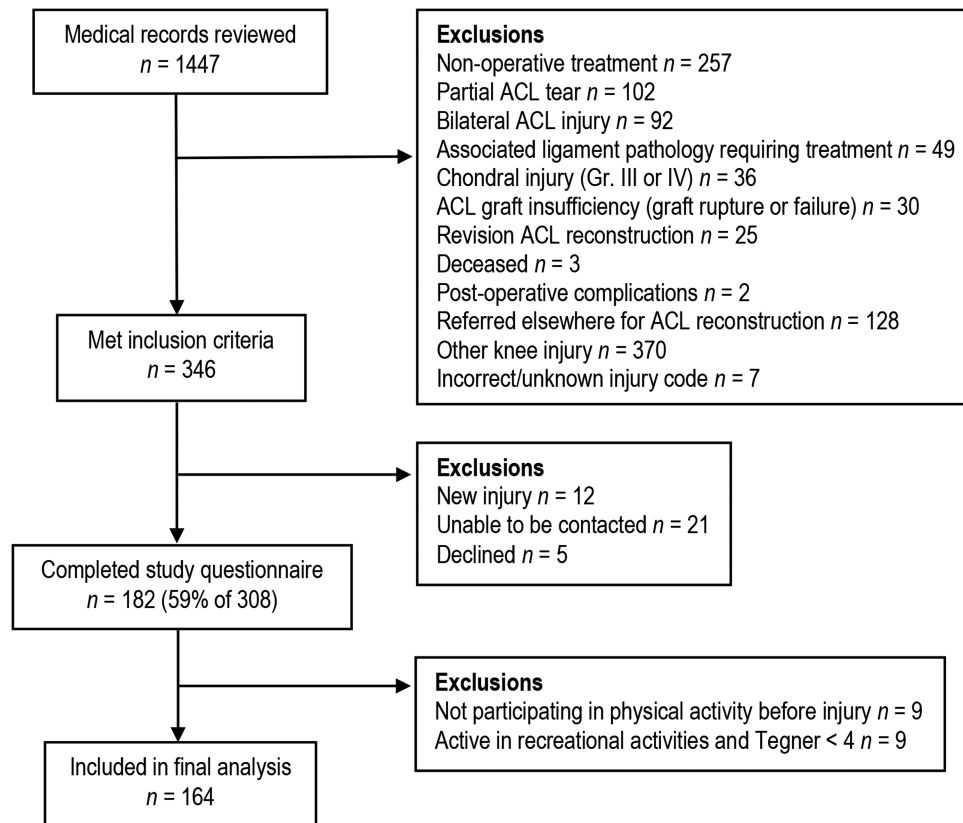

Figure 1 Participant identification (ACL, anterior cruciate ligament; Gr., grade).

recreational activities. The *Quality of Life* (four items) domain of the KOOS was used to evaluate knee-related quality of life.

The ACL–Quality of Life scale (ACL-QoL)²⁷ was used to evaluate knee-related quality of life specifically related to ACL injury.

Participants also rated their overall satisfaction with their current level of knee function on a 10-point, numerical scale written specifically for the current study.

Demographic factors

Age at follow-up, sex and the preinjury activity level, self-reported by participants as elite, subelite competitive or recreational level activity, were analysed.

Statistical analysis

All analyses were completed using SPSS V20.0 (IBM Corp, Armonk, New York, USA); and a list-wise deletion approach was used to deal with missing data. The psychological factors evaluated were knee self-efficacy, health locus of control, psychological readiness to return to sport and recreational activity, and fear of reinjury. The appraisal of knee function factors were knee function during sport and recreational activities, knee-related quality of life and satisfaction with knee function.

Between-groups analyses

A p value of ≤ 0.05 was used to indicate statistical significance. Descriptive statistics were calculated for all explanatory variables and compared between participants who had and had not returned to their preinjury sport or recreational activity, to give an overall impression of differences in individual patient-reported outcomes between those who had and had not returned to activity. Age was dichotomised based on the median age of the cohort. Between-groups comparisons were made

using χ^2 tests, and independent samples t tests or Mann-Whitney U tests as appropriate. α Corrections for multiple comparisons were made using Benjamini and Hochberg's²⁸ false-discovery rate method, which has been advocated for use in health research in place of Bonferroni adjustments.²⁹ Unadjusted and adjusted p values were calculated and presented to provide an indication of the likelihood of type I and II error rates; given that it has been previously argued that minimisation of the likelihood of type II error is preferable in exploratory research.^{30 31}

Multivariable analyses

Binary logistic regression was used to determine the factors associated with returning to the preinjury sport or recreational activity. Return to the preinjury activity (yes or no) was the outcome variable.

A two-stage process was used to determine the psychological and appraisal of knee function explanatory variables to be included in the final model. First, simple regression analyses, where individual explanatory variables were regressed on the outcome variable were used to identify the psychological and appraisal of knee function factors to be included in the second stage. A significance level of ≤ 0.10 ³² was used to decide whether individual variables were retained. At this stage, all subscales of the MHLC scale (*Internal, Chance, Doctors and Others*) were excluded from further analysis. The explanatory variables that were retained were checked for multicollinearity using the linear regression method.³³ A Variance Inflation Factor of > 5 was used to denote significant multicollinearity. The ACL-QoL scale was excluded from further analyses due to significant multicollinearity. Then, the remaining explanatory variables were entered into a backward stepwise model. A significance level of ≤ 0.05 was used to identify variables that

would be retained for the final model. Outliers were excluded based on a standardised residual of >3 . Using this criterion, one outlier was excluded from the final model.

For the final model, the explanatory variable(s) that were retained were entered with the demographic age, sex and preinjury activity level. Time between surgery and follow-up (months) was also included as an independent adjusting variable in the final model; interactions between explanatory variables were also examined.

RESULTS

Ninety-nine men (median age 28 years) and 65 women (median age 24 years) with a median age of 26 years (range 18–45 years) at the time of follow-up were included. The majority of participants were active at a subelite competitive level (64%) prior to their ACL injury; 24 participants (15%) were active at an elite competitive level and the remaining 35 (21%) were active at a recreational level. At the time of ACL injury, participants were most commonly participating in football ($n=83$, 52%), floorball ($n=20$, 12%) or handball ($n=8$, 5%). At follow-up, 66 participants (40%) had returned to their preinjury sport or recreational activity, and the rate of return to activity was not associated with age, sex or preinjury activity level (table 1).

Among the top three sports most frequently participated in (football, floorball and handball), approximately one in three people had returned to their preinjury activity participation (table 2).

The three most common reasons for not returning were a lack of trust in the knee ($n=25$ of 88, 28%), fear of sustaining a new injury ($n=21$ of 88, 24%) and poor knee function ($n=19$ of 88, 22%; table 3).

Between-group comparisons

There were significant differences in psychological and appraisal of knee function factors between participants who had and had not returned to their previous sport or recreational activity (table 4). Participants who had returned to their previous activity reported higher knee self-efficacy (K-SES); greater psychological readiness to return to sport and recreational activity

Table 2 Frequency of returning to preinjury sport or recreation activities by sport

statistical criteria for inclusion in the final model ($B=0.59$, $Wald=27.7$, $p<0.0001$, OR , 95% $CI=1.8$, 1.4 to 2.2).

The final model ($\chi^2_{(5)}=48.3$, $p<0.001$; Nagelkerke $R^2=0.36$) demonstrated that ACL-RSI score and time between injury and follow-up made significant independent contributions to explaining approximately 36% of the variance in returning to the preinjury sport or recreational activity. For every one point increase in ACL-RSI scale score, there was approximately twice the odds of returning to the preinjury activity. For every month increase in time to follow-up, the odds of returning to sport or recreational activity reduced by 3% (table 5). There were no significant interaction effects between ACL-RSI scale score and time to follow-up, age, sex or preinjury activity level; and no main effects of age, sex or preinjury activity level on returning to the preinjury sport or recreational activity (table 5).

DISCUSSION

Participants who had returned to their preinjury sport or recreational activity had more positive responses to the psychological outcomes, a higher knee-related quality of life and self-reported knee function, were more satisfied with their current knee function, and reported better knee function in sport and recreational activities compared with those who had not returned. The factor most strongly associated with returning to the preinjury activity was the ACL-RSI scale, which evaluates psychological

readiness to return to sport and recreational activity after ACL reconstruction. There were reduced odds of returning with increasing time between surgery and follow-up; and age, sex and preinjury activity level were not related to returning to the preinjury sport or recreational activity.

In the current study, psychological readiness to return to sport and recreational activity (measured with the ACL-RSI) was the factor most strongly associated with returning to the preinjury activity. In line with that, in two previous studies of competitive and recreational level athletes, the ACL-RSI has been identified as the best predictor of returning to the preinjury level sport at 12 months after ACL reconstruction.^{5 34} The scale is a condition-specific measure of psychological readiness (structured under the concepts of emotions, confidence and risk appraisal) and the current results provide further evidence of the construct validity of this scale. The specificity of this scale to the population, and the fact that the scale specifically addresses psychological factors related to performing sport and recreational activities may support its use as a key patient-reported outcome after ACL reconstruction.

The rate of return in the current study is similar to a previous study that evaluated the return to sport rate at 2–7 years following ACL reconstruction in an Australian population.⁴ In the Australian study, 45% of athletes had returned to their preinjury sport at follow-up. The authors also noted that some athletes returned to sport after reconstruction, then stopped participating. Promoting life-long participation in physical activity may be an important means of maintaining physical and mental health,³⁵ and reducing chronic disease.^{36 37} Therefore, identifying the key factors that impact on returning to sport and recreation activities may be important so that physical activity promotion efforts may be directed towards addressing the factors relevant to those who do not return to activity.^{5 34}

Previously reported minimum detectable change (MDC) scores for the KOOS *Sport* (range 5.8–12 points out of 100 points) and *Quality of Life* (range 7–7.2 points out of 100 points) domains,³⁸ and the ACL-RSI (0.3 points out of 10 points)²³ (MDC scores for other patient-reported outcomes have not been published) could suggest that the statistically significant differences in patient-reported outcomes, observed in the univariate analyses, between participants who had and had not returned to their preinjury activity may have clinical significance.

Table 5 Regression model of the relationship between returning to the preinjury sport or recreational activity, and psychological and demographic factors

| Variable | B | SE | Wald statistic | p Value | OR (95% CI) |
|---------------------------------|-------|------|----------------|---------|----------------------|
| ACL-RSI | 0.67 | 0.12 | 31.2 | <0.001 | 1.95 (1.5 to 2.5) |
| Time to follow-up | –0.03 | 0.02 | 4.7 | 0.03 | 0.97 (0.94 to 0.997) |
| Age | –0.39 | 0.43 | 0.82 | 0.37 | 0.68 (0.3 to 1.6) |
| Sex | 0.28 | 0.41 | 0.46 | 0.50 | 1.32 (0.3 to 1.6) |
| <i>Preinjury activity level</i> | | | | | |
| Elite | | | 1.3 | 0.52 | |
| Competitive | –0.61 | 0.57 | 1.15 | 0.28 | 0.54 (0.2 to 1.7) |

ACL-RSI, Anterior Cruciate Ligament -Return to Sport after Injury scale.

However, while there was an association between returning to sport or recreational activity, and psychological factors including self-efficacy (measured with the K-SES) and appraisals of knee function (measured with the *Sport* domain of the KOOS) in the between-group comparison, these factors were not significant in the regression analysis. This could be because, in contrast to the ACL-RSI, the K-SES and KOOS *Sport* scales are not sport-specific. Given that an individual's confidence in performance of tasks (self-efficacy) is theorised to be situation and task specific,³⁹ and that performance in tasks such as squatting, kneeling, twisting and turning may be important for occupational functioning as well as for sport and recreation, this may explain the lack of association of the K-SES and KOOS *Sport* with returning to sport and recreational activities in the regression analysis.

There are limited data regarding the reasons why people do not return to preinjury activity following ACL reconstruction. Some previous studies have shown that knee function and a fear of reinjury are frequently cited as the reasons for not returning after ACL reconstruction.^{4 11 13 40} Around one in two participants in the current study who did not return to their previous activity cited a lack of confidence in the knee or fear of sustaining a new injury as the main reason for not returning. Around one in five reported that the main reason for not returning was poor knee function. It might be reasonable to expect that family or work commitments could contribute to people not returning to their previous activity. However, only approximately 1 in 10 participants who did not return to their previous activity reported work or family commitments as the primary reason for their non-return. This could suggest that the most important factors influencing the decision to return may be related to the individual's appraisal of their capacity to participate and the risks associated with participating. From the clinician's perspective, these findings may suggest that addressing psychological factors, including fear and confidence in postoperative rehabilitation, could have merit in helping people return to their preinjury sport or recreational activity. However, further research is required to test this hypothesis.

We found no influence of age on returning to sport or recreational activity. In contrast, recently, an association between younger age and an increased likelihood of returning to the previous activity has been demonstrated.^{4 13 41} One possible explanation for this discrepancy could be that there are geographical differences in the treatment of acute ACL injuries. In Sweden, where the current study was conducted, patients with acute ACL injuries routinely complete a 3–6-month period of rehabilitation before a decision is made regarding ACL reconstruction.⁴² Reconstruction is typically recommended to young patients and to older patients with symptomatic instability.⁴² It could be speculated that older patients who elect for reconstruction following the completion of the initial rehabilitation programme may have greater motivation to return to their previous sport or recreational activity; and this may help to explain why the rate of return to activity was similar across the age groups.

Most of the previous literature has evaluated physical impairments after ACL reconstruction. Strength of the current study is that by evaluating several psychological factors, appraisal of knee function and demographic factors, and using a multivariable analysis, it takes into account the multifactorial nature of returning to the preinjury sport and recreational activity after ACL reconstruction. This is important given that previous research has tended to evaluate single factors. In addition, the

current study examined the reasons for not returning to the preinjury activity.

A limitation of this study was that only 59% of potential participants responded to the battery of patient-reported outcomes. It is possible that, given the number of patient-reported outcomes included in the battery, some participants were deterred from completing it. Non-responders may have had a different rate of return to the preinjury sport and recreational activity, responses to the psychological outcomes and appraisal of knee function, than those who responded to the battery of outcomes. However, this response rate is comparable to a previous report of return to sport rates at 2–7 years after ACL reconstruction surgery,⁴ and above the 50% minimum suggested to reduce bias.^{43 44}

The population in the current study is heterogeneous in terms of preinjury sport and recreational activity participation. However, it is important to note that the sport and recreational activities participated in reflect the typical distribution of activities played at the time of ACL injury, reported in the Swedish National ACL register.⁴⁵ Activities that place higher demands on the operated knee, such as competitive football, may be more challenging for people to return to in comparison with activities such as recreational cycling that place lower demands on knee function.⁴⁶ Further research is required to explore differences in the rates of return to the preinjury activity following ACL reconstruction in different sport and recreational activities with different physical demands.⁴⁶ The cross-sectional design of the current study means that it is not possible to determine whether positive psychological factors and better appraisal of knee function predict returning to the preinjury sport and recreational activity. In addition, we chose to focus on one group of non-physical factors, psychological factors, as it was beyond the scope of this study to investigate all the factors that could impact on returning to sport and recreational activities (physical and non-physical). Therefore, consideration of the impact of other factors not evaluated in the current study may be warranted in future prospective studies.

As time from surgery to follow-up increased, the odds of returning to the pre-injury activity decreased, which may suggest that for some, other commitments took priority over participating in sport and recreational activity. It is also possible that some participants may have returned to sport or recreation early after surgery and ceased participation before follow-up or changed to participate in a different activity. However, further research is necessary to confirm these hypotheses.

What are the new findings?

- ▶ Psychological readiness to return to sport (measured with the Anterior Cruciate Ligament-Return to Sport after Injury (ACL-RSI) scale) was the factor most strongly associated with returning to the preinjury sport or recreational activity after ACL reconstruction.
- ▶ Age, sex and preinjury activity level were not associated with returning to the preinjury sport or recreational activity.
- ▶ The most common reasons given by participants for not returning to the preinjury activity were: not trusting the knee, fear of another injury and poor knee function.

How might it impact on clinical practice in the near future?

- ▶ A stronger and more systematic emphasis on addressing psychological readiness to return to activity in postoperative rehabilitation programmes could be warranted to help improve returning to activity after ACL reconstruction.
- ▶ Patients reporting a lack of confidence in the knee or fear of sustaining a new injury may be at increased risk of not returning to their preinjury sport or recreational activity, and could require additional support during rehabilitation.
- ▶ Clinicians may wish to consider the use of the ACL-RSI scale as a key patient-reported outcome after ACL reconstruction.

Acknowledgements The authors thank Henrik Magnusson at Linköping University for statistical support; and Professor Gerhard Andersson at Linköping University for advice on interpretation of the results.

Contributors All authors contributed to the design of the study. AÖ was responsible for participant recruitment, and JK and AÖ for data collection. CLA, JK and AÖ analysed the data. CLA and AÖ drafted the manuscript, and JK, HG, ST and KEW revised it for important intellectual content. All authors approved the final manuscript. CLA is responsible for the overall content as the guarantor.

Competing interests None.

Ethics approval Regional Ethics Committee at Linköping University (approval number 2012/425-32).

Provenance and peer review Not commissioned; externally peer reviewed.
